

The Water Level at Deep Creek Lake

Pete Versteegen and Morgan France

I. Introduction

There is a great deal of confusion and misinformation floating around regarding the water level at Deep Creek Lake. This report documents the voluntary unpaid research performed by the authors to clarify some of the issues on this subject.

This clarification is done in the form of understanding the water budget of the lake; where does the water come from and where does it go. Understanding the water budget requires an evaluation of existing data and of modeling the water level of the lake. The challenge is to first find reliable measurements of various kinds, including weather and water levels, understand the meaning of the data, and develop a model that reflects the physical behavior of the lake.

This is a preliminary report. Much more work remains to be done, but we feel that it is important to report our findings before expensive api work gets done that may not address the issues properly.

We're going to start out small and the whole will hopefully evolve into a tool and an approach that can be used reliably and with insight.

Objectives

The principal objective of this effort is to devise an approach that can accurately predict the lake's water level given a set of basic, readily obtainable, information. The target is to be able to predict the water level at any time within 1/2 of a foot.

2. Factors Affecting the Lake Water Level

Let's first list the factors that affect the lake water level. There is no ordering in the list as to what is more important. It's just a list whose items need to be examined in detail. As with all things in science certain factors are related and dependent on others. We hope to tease all these apart.

I. Incoming Flows

1. Rain directly on the lake surface

This speaks for itself. It should be noted that, from observations, when it rains, the rain only falls on parts of the lake.

2. Rain on the watershed

["A watershed is the area of land where all of the water that is under it or drains off of it goes into the same place."](#)

In general this would mean a continuous ridge of high ground that divides to drainage areas. that divide a region. This rain is typically

absorbed by the land and only gets in the lake proper if the soils are saturated. Some of this rain falls on impervious surfaces and flows into the lake in the form of storm-water runoff.

3. Inflow from creeks

Creeks derive their water from springs, storm-water runoff and groundwaters. Their flows are therefore connected to the processes taking place under item 2 above.

4. Flow from springs under the lake bed

These would be very difficult to quantify, but there are known springs on the lake bed.

5. Runoff from melting snow off the Wisp ski slopes

Wisp pumps water from the lake into holding reservoirs from which it is pumped to make snow. When the snow melts much of it goes as storm water runoff into the lake. Some will recharge groundwater, and some will evaporate. The partitions are clearly unknown.

6. Groundwater

As the lake level falls down, groundwater from beyond the shores enter into the lake recharging it to some extent. There are a few experiments that were performed by USGS that show that water wells on land follow lake level. Hence pumping from these wells also means drawing water from the lake.

2. Outgoing Flows

1. Evaporation

The lake has a large surface area and it stands to reason that evaporation can be important. To our knowledge there are no measurements of that affect for Deep Creek Lake. It is affected by air-water temperature differences, the humidity of the air, solar radiation, and wind speed.

Evaporation takes place in different areas, and each will require a different model. We're concerned with:

1. Lake water evaporation

2. Canopy evaporation

2. Releases thru the hydro-electric turbines

To a limited extent, Deep Creek Lake levels can be controlled by the Deep Creek Hydroelectric Station which operates under a Water Appropriation and Use permit from the Maryland Department of the Environment (MDE). Under the permit conditions, the Station, which is owned by Brookfield Renewable Power, uses water to generate hydropower, but keeps lake levels within a defined "rule band" with upper and lower limits. The permitted release schedule can be found

[here](#). The parameters of the plant are well [published](#), but perhaps not verified.

1. Leakage around the hydro-electric plant

Various leakages have been mentioned, penstock, wicket gate, but not quantified, nor how long they have existed. Brookfield (and Pennelec) records should provide some insight.

2. Leakage through the dam

The dam is across Deep Creek. There still exists a stream beyond the dam.

3. Permitted removal

Several permits exist to draw water from Deep Creek Lake. The companies [permitted](#) to withdraw water from the lake are:

1. Brookfield Power for the hydroelectric project
2. Recreational Industries for irrigation of the golf courses, providing water to ASCI and for snow making
3. Thousand Acres for irrigation of the golf course
4. MDE/DNR for temperature enhancements for fish in the Youghiogheny river and white water recreational activities on the Youghiogheny river

Their withdrawal rate is unknown, except for the permit levels.

3. Analysis Philosophy and Approach

We wished to keep things simple. Our approach to understanding the water budget revolved around the following ideas:

1. Gather measured information and assess their reliability
2. Identify correlations among the data
3. Develop a simple model of the water budget

Each of these points are discussed below.

1. Data

Calculating a viable water budget for the lake, with any tool, requires a certain amount of reliable data. This section lists the kind of data required. Unless mentioned otherwise, we were seeking a complete data set for the year 2011, Jan 1-Dec 31, 2011. For our current purposes, we were looking for daily average data. But, anything on a smaller time scale is clearly usable since we can create the daily averages from that. Hopefully such data is digital, but equations are also acceptable.

So here is the list.

1. Weather Data

Weather data are needed to provide precipitation, rain and snow, as direct contributors for water to the lake and from its watershed. Lake-water evaporation requires air temperature, solar insolation, windspeed, and relative humidity.

2. Water Temperatures

Water temperatures of the lake are needed to compute evaporation and the mixed temperature of the lake and Youghiogheny river water temperature. Water temperature of the Youghiogheny river is needed to compute the above mentioned mixed temperature to assess the need for “enhanced temperature releases” by the hydro plant

3. Water Levels

This is the crucial data set needed to verify the operability of the model, and to assist in deriving certain model parameters.

4. Bathymetry

The bathymetry is needed to determine the lake volume at any time, as a function of water level.

5. Well Data

Well data is necessary to determine the extent of groundwater connectivity to the lake and the true ‘capacity’ of the lake.

We’ve made significant progress in all of these areas.

Weather Data

We have tracking down pretty much all of the weather data that exists for the area. Appendix A provides a detailed listing do data sources.

The most reliable current data is from the McHenry airport. Their weather station means aviation standards and is checked and calibrated, if necessary, quarterly. It is close to the lake and for most of the measurements it should be representative of conditions a the lake.

Unfortunately, the most important item is missing, precipitation data.

Water Temperatures

We have not paid much attention to this topic, since it is currently of no direct consequence.

Water Levels

We were not able to readily find historic water level data. However, we have been able to collect extensive data on water level via the power station’s website. The methods are described in Appendix B. This data has provided us with some

significant insight as to what is going on with the water in the lake. This is discussed later on in the results section.

Bathymetry

Well Data

2. Modeling

The State of Maryland, via USGS, has a number of modeling tools for computing and tracking the water budget and water quality of the lake. Being in a position to use them correctly and with confidence is beyond our scope and desire. We have chosen [Simgua](#) as the tool to do our modeling. Simgua belongs to a category of computer programs called “System Dynamics.” It’s a mathematical modeling technique that can be used to examine the time dependent behavior of complex systems. Other tools of this genre include [Stella](#), [Vensim](#), and others. For a historical background of this technology see the [article in Wikipedia](#). Simgua is a Mac OS X tool only. Models in Simgua are built along the concepts of stocks, flows and feedback, as with the other simulation tools. It’s extremely easy to use and has a very friendly user interface.

While Simgua is the simulation tool, to make it do its work correctly we need models for the different phenomenologies that take place in creating the water budget. This section describes the models that will be used initially. As we gain more experience, other models may be used, or we may extend the existing models.

The lake is a dynamic system. While intrinsically possible, the simulations should probably be done on an hourly basis, given that water releases are defined in terms of hours. Given the status of the needed data and the desired accuracy, average daily flows and conditions should probably be adequate. Hence, that will be our initial focus.

4. Description of Deep Creek Lake

A detailed description of Deep Creek Lake is provided in Appendix x.

5. Results

This section describes the results that have obtained so far.

Modeling

As described about, Simgua has been used to do modeling of the water budget. A very simplistic approach has been used initially. The initial equation set solved is:

$$A_L \frac{dH}{dt} = -Q_t + Q_{gw}$$

$$\frac{dQ_{gw}}{dt} = c_L P_L (H_0 - H)$$

Where:

A_L = Area of the lake, acres

H = Lake level, ft

t = time, min

Q_t = Flow rate through the turbines, ft³/sec

Q_{gw} = Groundwater recharge flow rate, ft³/sec

P_L = Perimeter of the lake, ft

H_0 = Reference head for Darcy type flow, ft

C_L = Coefficient describing Darcy law hydraulic conductivity, min⁻¹

The time step used by Simgua was 'minutes.;' volume flows were in acre-ft, levels in ft.

The model as displayed by Simgua is shown in Figure 1.

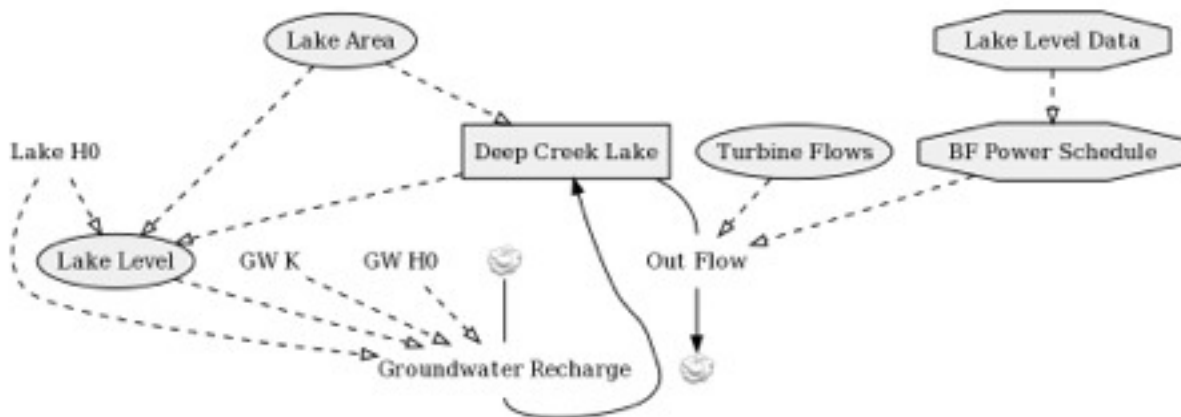

Figure 1 - Simgua Model of the Lake

For a 2600 minute duration and using the following parameters:

$A_L = 3900$ acres, $Q_t = 2 \times 300$ cfs, $P_L = 65$ miles, $H_0 = 2458$ ft, $C_L = 0.02$ /min,
figure 2 shows the predicted time behavior of the lake level.

Figure 2 - Predicted Lake Level

The corresponding generator status is shown in Figure 3.

Figure 3 - Generator status for the simulation
